We study structure and direct decay of the Giant Monopole Resonance (GMR) using the Time-Dependent Energy-Density-Functional method in the linear response regime in a few doubly-magic nuclei. In these calculations, a proper treatment of the continuum, through the use of large coordinate space, allows for a separation between the nucleus and its emitted nucleons. The microscopic structure of the GMR is investigated with the decomposition of the strength function into individual single-particles quantum numbers. A similar microscopic decomposition of the spectra of emitted nucleons by direct decay of the GMR is performed. Shifting every contribution by the initial single-particle energy allows to reconstruct the GMR strength function. The RPA residual interaction couples bound 1-particle 1-hole states to unbound ones, allowing for the total decay of the GMR.

I. INTRODUCTION

Atomic nuclei are known to exhibit a wide range of collective excitations [1]. Amongst them, giant resonances (GRs) are of particular interest in our understanding of collective motion in nuclei. Macroscopically, they are associated to high energy modes of small amplitude vibration of the entire nucleus. Microscopically, they can be described, in a first approximation, by coherent superpositions of one-particle one-hole (1p1h) excitations [2].

Giant resonances lie usually at energies above the light particle emission threshold. Different kinds of decay are commonly distinguished. For instance, direct decay occurs when one particle is emitted leaving the daughter nucleus in a single hole state. However, the decay is sequential when two-particle two-hole (2p2h) configurations are populated by the residual interaction. The direct decay by nucleon emission is of particular interest as the emitted nucleon can give a glimpse on the microscopic structure of the GR. As such, it is an experimental tool of choice to study GRs (see, e.g., Refs. [2–5]).

Collective motion in nuclei can be investigated with microscopic theories based on time-dependent Energy-Density-Functional (TD EDF) approaches. In particular, the time-dependent Hartree-Fock(-Bogoliubov) equations in their linearized version (Q)RPA [6, 7], have been widely used to study various GR strength distributions (see [8, 9] and references therein). When a proper treatment of the continuum is accounted for, those methods are also capable of describing direct neutron and proton decay.

The goal of the present work is to investigate the link between the 1p1h structure of giant resonances and their direct-decay pattern. The scalar-isoscalar Giant Monopole Resonance (GMR) is studied in several closed-shell nuclei. The response to a scalar monopole excitation in the small amplitude regime is computed using the time-dependent Hartree-Fock (TDHF) formalism [10], based on a modern Skyrme functional [11]. To study

GMR direct-decay, the calculations are performed in a large spherical grid, allowing for a spatial separation of the nucleus from the emitted nucleons to the continuum. Similar TDHF calculations have been performed in the past with schematic energy density functionals to study GMR widths and lifetimes from direct decay [12, 13]. These quantities were extracted from the time evolution of the number of emitted nucleons. In the present paper, new informations are obtained by computing energy spectra of the nucleons which are emitted in the direct-decay of the GMR. The structure of these spectra is then analyzed in terms of single-hole configurations of the $A-1$ daughter nucleus.

Theoretical framework and numerical details are presented in section II. Results obtained on several closed-shell nuclei are discussed in section III before concluding in section IV.

II. THEORETICAL FRAMEWORK AND NUMERICAL DETAILS

A. Time-dependent Hartree-Fock approach for collective vibrations

The TDHF equation reads [6]

$$i\hbar \frac{d}{dt} \rho = [h[\rho], \rho], \quad (1)$$

where ρ is the one-body density matrix and $h[\rho]$ is the single-particle hamiltonian derived from the energy density functional $E[\rho]$ using

$$h_{ij}[\rho] = \frac{\delta E[\rho]}{\delta \rho_{ji}}. \quad (2)$$

In the TDHF theory, the many-body state is constrained to be an independent particle state (e.g., a Slater determinant of the occupied single-particle states) which implies $\rho^2 = \rho$ at all time.

The one-body density matrix is used to compute expectation value of one-body operators for which TDHF is optimized [14]. Information on vibrational modes such as energy can then be obtained through the evolution of their corresponding multipole moment. For instance, the excitation of a monopole mode $|\nu\rangle$ on top of the ground state induces an oscillation of the expectation value of the monopole moment [6, 7]

$$\hat{F} = \sum_{\sigma,q} \int r^2 \hat{a}_{\mathbf{r}\sigma q}^\dagger \hat{a}_{\mathbf{r}\sigma q} d\mathbf{r} \quad (3)$$

where $\hat{a}_{\mathbf{r}\sigma q}^\dagger$ ($\hat{a}_{\mathbf{r}\sigma q}$) creates (annihilates) a nucleon in $\mathbf{r}$ with spin σ and isospin q . In this mode, $\langle \hat{F} \rangle(t)$ oscillates at a frequency $\omega_\nu = (E_\nu - E_0)/\hbar$, where E_0 is the ground state energy and E_ν the energy of the excited state.

The linearization of the TDHF equation leads to the RPA [6]. As a consequence, TDHF calculations in the small amplitude limit contain all the RPA residual interaction which is responsible for the collectivity of giant resonances. Using TDHF codes ensures that the same EDF is used to determine both the HF ground-state and the dynamics thanks to the structure of the TDHF equation. It is then equivalent to fully self-consistent RPA codes.

In addition to energies of GRs, TDHF has been used to study their strength distribution [15–22], their life-time and escape width [12, 13], and their anharmonicities [23–25]. Escape width and Landau damping are accounted for in TDHF, however, two-body correlations responsible for the spreading width are neglected. Inclusion of pairing correlations is possible in the TDHF-Bogoliubov theory [6, 7], however its numerical applications [9, 26] are time-consuming and prevent the use of large spatial grid as in the present study.

B. Linear response theory

The nucleus is assumed to be in its ground state at initial time. An external field $\hat{V}_{ext} = \epsilon \eta(t) \hat{F}$ is applied, where ϵ is the intensity of the perturbation and $\eta(t)$ is its time profile. We choose a delta-function for the latter: $\eta(t) = \delta(t)$. The evolution of an observable $\delta Q(t) = \langle \hat{Q} \rangle(t) - \langle \hat{Q} \rangle_0$ in the linear regime, where $\langle \hat{Q} \rangle_0$ is the expectation value on the ground state $|0\rangle$, can be written

$$\delta Q(t) = \frac{\epsilon \Theta(t)}{i\hbar} \sum_\nu \langle 0 | \hat{Q} | \nu \rangle \langle \nu | \hat{F} | 0 \rangle e^{-(\lambda_\nu + i\omega_\nu)t} + c.c., \quad (4)$$

where $\Theta(t) = 0$ if $t < 0$ and 1 if $t \geq 0$, $\{|\nu\rangle\}$ are the eigenmodes, and *c.c.* stands for *complex conjugated*. For bound states, $\lambda_\nu = 0$, while unbound states decay with a lifetime $1/\lambda_\nu$. To analyze the spectral response of δQ , we introduce the quantity

$$R_Q(\omega) = \frac{-\hbar}{\pi\epsilon} \int_0^\infty \delta Q(t) \sin(\omega t) dt. \quad (5)$$

which, in the particular case where $\hat{Q} = \hat{F}$, reduces to the strength function. For bound states, the latter reads

$$R_F(\omega) = \sum_\nu \left| \langle 0 | \hat{F} | \nu \rangle \right|^2 \delta(\omega - \omega_\nu), \quad (6)$$

while a Lorentzian width appears for finite values of λ_ν in the continuum.

C. Monopole vibrations in spherical symmetry

The monopole moment of Eq. (3) is used in the external field. Assuming spherical symmetry of the ground state, only monopole modes are excited. It is then convenient to decompose the response of the nucleus in terms of the usual quantum numbers l and j using the operators

$$\hat{F}_{lj} = \sum_{n,n',m_j} \langle nljm_j | \hat{F} | n'ljm_j \rangle \hat{a}_{nljm_j}^\dagger \hat{a}_{n'ljm_j}, \quad (7)$$

where the isospin is omitted to simplify the notation. The spectral response, $R_{F_{lj}}(\omega)$, defined in Eq. (5), can then be used to analyze microscopically the strength distribution of the GMR.

D. Spectra of emitted nucleons

The energy spectra of emitted (free) nucleons can be computed by evaluating overlaps between the single-particle wave-functions $\varphi_{nljm_j}(\mathbf{r}\sigma)$ (with degeneracy $2j+1$ in spherical symmetry) and spherical plane waves $\phi_{kljm_j}(\mathbf{r}\sigma)$ of energy $E = \frac{\hbar^2 k^2}{2m}$, where m is the nucleon mass. The latter read

$$\phi_{kljm_j}(\mathbf{r}\sigma) = \frac{1}{\mathcal{N}} j_l(kr) \Omega_{ljm_j}^\sigma(\theta, \phi), \quad (8)$$

where $j_l(kr)$ is a spherical Bessel function for angular momentum l and momentum k , $\Omega_{ljm_j}^\sigma(\theta, \phi)$ is a spherical spinor [27], and $\mathcal{N}$ is a normalization constant. The overlaps between a single-particle wave-function and a spherical plane wave with the same l, j and m_j thus reads

$$c_{ljm_j}^n(k) = \sum_\sigma \int \phi_{kljm_j}^*(\mathbf{r}\sigma) \varphi_{nljm_j}(\mathbf{r}\sigma) d\mathbf{r}. \quad (9)$$

The probability to find a nucleon with energy E and quantum numbers l and j is given by

$$\rho_{lj}^\uparrow(E) = \sum_n \sum_{m_j=-j}^j \left| c_{ljm_j}^n(k) \right|^2. \quad (10)$$

E. Numerical details

The evolution of the occupied single-particle wave-function is determined from the TDHF equation in a

spherical mesh of radius $R_{box} = 600$ fm, with a radial spacing $\delta r = 0.3$ fm and hard boundary conditions. The SLy4 parametrization [28] of the Skyrme EDF [11] is used. In a first step, the HF initial condition is computed in a $R_0 = 30$ fm box with the same radial spacing. At initial time, all single-particle wave-functions vanish for $r > R_0$.

In principle, the nucleon spectrum should be determined at large distances from the nucleus to avoid any long-range interaction with the latter. In practice, the integral in Eq. (9) is performed from R_0 to R_{box} . Note that the upper limit of the integral in the definition of the monopole moment in Eq. (3) is chosen to be R_0 to avoid a divergence of δF due to emitted nucleons.

To account for the finite size of the box, only spherical plane waves vanishing at R_{box} are considered in Eq. (8). (Their normalization constant $\mathcal{N}$ is determined assuming that they vanish for $r \geq R_{box}$). As a consequence, the momentum of each partial wave with quantum number l can take only discrete values. To avoid spurious peaks from this discretization, $\rho_{lj}^\dagger(E)$ is convoluted with a normalized Gaussian distribution in energy with a standard deviation of 150 keV.

III. RESULTS

A. Detailed analysis of the GMR in ^{16}O

To illustrate the method, let us start with a microscopic analysis of the GMR direct decay in ^{16}O . The evolution of the expectation value $\delta F(t) = \langle \hat{F} \rangle(t) - \langle \hat{F} \rangle_0$ of the observable $\hat{F}$ given in Eq. (3), where the integral is performed up to R_0 , after a monopole excitation in linear regime is shown in Fig. 1. A damped oscilla-

FIG. 1: Evolution of the monopole moment in ^{16}O after a monopole boost in linear regime.

tion associated to the GMR is observed, with an average period $T_{GMR} \simeq 57.9$ fm/c corresponding to an energy $E_{GMR} = 2\pi\hbar/T_{GMR} \simeq 21.4$ MeV. In a coherent state picture (see, e.g., [29]), the number of excited phonons is

proportional to the square of the oscillation amplitude. The damping of the oscillation is then a signature for GMR decay. Here, the decay occurs by nucleon emission as E_{GMR} is greater than the proton and neutron separation thresholds in ^{16}O . The description of nucleon emission is possible if the continuum is properly accounted for. This is ensured, here, by the large size of the spherical mesh to prevent spurious effects coming from reflected flux on the edge of the box [30].

The strength function associated to $\delta F(t)$ and obtained from Eq. (5) with $Q = F$ is plotted in Fig. 2 (black solid line). The main peak at $\sim E_{GMR}$ is surrounded by two shoulders at ~ 17 and ~ 31 MeV. In order to get a deeper insight into the microscopic origin of these structures, the spectral responses of the $\delta F_{lj}(t)$ [see Eq. (7)] following the same monopole boost are computed from Eq. (5) and plotted with colored lines in Fig. 2. We have checked numerically that the sum of these spectral functions is equal to the total strength function R_F , as expected. This decomposition shows that the low-energy shoulder and the main peak are mainly due to $p_{1/2}$ and $p_{3/2}$ orbitals, respectively. The structure of the high-energy shoulder is more complicated. It involves a constructive contribution of the $s_{1/2}$ orbitals while the $p_{3/2}$ ones reduce the strength in this region. The dominant role of the $s_{1/2}$ neutron and proton contributions in the high-energy shoulder has already been noted using similar techniques but other EDF parametrizations [13, 22].

FIG. 2: (Color online) Strength function of the GMR in ^{16}O (black solid line) computed from the time evolution of the monopole moment $\delta F(t)$. The spectral responses $R_{F_{lj}}$ associated to the single-particle quantum numbers l and j and labelled by their spectroscopic notation are plotted in colored solid (dashed) lines for neutrons (protons).

The next step of our analysis is to study the decay properties of the GMR and to investigate their relationship with the previous microscopic decomposition. The spectra of emitted nucleons are computed 2250 fm/c after the boost, e.g., when the monopole oscillation is fully damped (see Fig. 1). We use the method described in Sec. II D. The proton and neutron spectra for each set of l and j are plotted in Fig. 3. We have checked numerically

TABLE I: Energies (in MeV) of the occupied single-particle states in the HF ground state of ^{16}O .

s.p. state	proton	neutron
$1s_{1/2}$	-32.4	-36.2
$1p_{3/2}$	-17.1	-20.6
$1p_{1/2}$	-11.2	-14.5

that, in the linear regime, these spectra are quadratic in the intensity of the boost ϵ [12].

First we note that proton and neutron spectra have similar global features, as expected for light $N = Z$ nuclei, although the proton spectra are shifted by ~ 3 MeV due to the Coulomb repulsion. In addition, the Coulomb barrier, which is $B_c \simeq 1.7$ MeV in ^{16}O , reduces strongly the emission of protons at energy $E < B_c$ due to the exponentially decreasing tunneling probability. We also note that there is no relevant emission of $s_{1/2}$ orbitals. In fact, the single-particle energy of the $1s_{1/2}$ orbitals, which are the only occupied $s_{1/2}$ single-particle states in the HF ground-state of ^{16}O , are -32.4 MeV for protons and -36.2 for neutrons (see table I). As a result, the $1p1h$ states with a hole in a $1s_{1/2}$ orbital, and contributing to the GMR microscopic structure, are bound for neutrons and below B_c for protons. Indeed, the different structures in the GMR spectrum (see Fig. 2) are located at energies below ~ 33 MeV, which is not sufficient to emit a $1s_{1/2}$ single-particle.

FIG. 3: (*Color online*) Neutron (solid lines) and proton (dashed lines) direct-decay spectra of the GMR in ^{16}O for each set of single-particle quantum numbers l and j , given in spectroscopic notation.

Let us now attempt to reconstruct the GMR strength function from the spectra of emitted nucleons shown in Fig. 3. In a pure harmonic picture, the GMR is a coherent sum of $1p1h$ states with a difference $\sim E_{GMR}$ between the particle and the hole energies. However, the nucleon emitted by direct decay have only the energy of the particle-state, which is obviously smaller than E_{GMR} because the energy of the hole-state is negative. To re-

construct the GMR strength function, it is then necessary to shift the energy of the emitted nucleons by the energy of their associated hole-state, that is, the energy of the initially occupied single-particle state. The latter are given in table I for ^{16}O at the HF level. The "shifted" spectra of emitted nucleons for each set of l and j , noted $\rho_{lj}^{\dagger(s)}$, obtained from this procedure, are plotted in Fig. 4-b, together with their sum. It is striking to see that the shape of the latter is very similar to the strength function shown in Fig. 2 and recalled in Fig. 4-a, although the two spectra have been obtained from totally different quantities, i.e., the spectra of emitted nucleons and the time evolution of the monopole moment.

Similarly to the microscopic decomposition of the strength function obtained from the time evolution of the monopole moment (see Fig. 2), we see in Fig. 4-b that the low energy shoulder and the main peak are associated to $p_{1/2}$ and $p_{3/2}$ orbitals, respectively. Again, the situation for the high energy shoulder is more complicated. Although it is mainly due to $s_{1/2}$ orbitals in the monopole response (see Fig. 2), it is in fact associated to the emission of p -orbitals in Fig. 4-b. As discussed before, this is because the energy of the GMR is not sufficient to promote a $1s_{1/2}$ single-particle to the continuum. However, the RPA residual interaction couples the responses associated to the different single-particle quantum numbers to produce a collective monopole vibration. As a result, the vibration of s -orbitals can be coupled to p -unbound-states contributing to the direct decay. Such coupling might be the reason for the complex competition between constructive and destructive contributions in the high-energy shoulder observed in Fig. 2.

B. Tin isotopic chain

Similar analyses have been performed for the GMR in $^{100,132}\text{Sn}$ nuclei. The strength functions obtained from the time evolution of the monopole moment are plotted with black solid lines in the upper panels of Fig. 5 and 6. The reconstructed GMR strength, obtained from the emission spectra are plotted with black solid lines in the lower panels. As in the ^{16}O case, the agreement between the two methods is excellent.

The gross feature of the strength is similar for the two isotopes, with a single peak centered at $E_{GMR} = 17.2$ MeV for ^{100}Sn and 15.8 MeV for ^{132}Sn (see table II), although their widths vary more importantly. It is striking, however, that the decompositions in terms of single-particle quantum numbers exhibit some important differences between the two techniques. Although both proton and neutron single-particle orbitals participate to the vibration (see upper panels in Fig. 5 and 6), the decay only occurs by neutron emission for ^{132}Sn , whereas ^{100}Sn decays through proton emission only. This can be understood by the fact that the proton (neutron) separation energy increases (decreases) with the number of neutrons. These quantities are given in table II, together

FIG. 4: (Color online) (a) Strength function of the GMR in ^{16}O obtained from the time evolution of the monopole moment. (b) Spectra of emitted neutrons (colored solid lines) and protons (colored dashed lines) "shifted" by the energy of the initially occupied single-particle state (see text). Their sum is shown in black solid line.

TABLE II: Neutron and proton separation energies and Coulomb barriers in Sn isotopes. The GMR energy corresponds to the position of the peak in the strength function. All energies are in MeV.

	S_p	B_c	$S_p + B_c$	S_n	E_{GMR}
^{100}Sn	3.1	8.1	11.4	16.9	17.2
^{132}Sn	15.6	7.4	23.0	7.7	15.8

with the Coulomb barrier for protons and the position of the peak energy associated to the GMR energy. Indeed, the binding energy of neutrons in ^{100}Sn is of the order of E_{GMR} and proton emission is favored, while the combined effects of an increasing S_p and the Coulomb barrier B_c prevent proton emission in ^{132}Sn .

As in the case of the high-energy shoulder in the ^{16}O spectra of figures 2 and 4, the difference in the microscopic decomposition of the GMR strength with the two techniques is a signature of the RPA residual interaction which couples the bound particle-hole states to the unbound ones, allowing their decay. In particular, the vibration of the protons (neutrons) in ^{132}Sn (^{100}Sn) decays via neutron (proton) emission thanks to the collective vibration of both proton and neutron mean-fields.

FIG. 5: (Color online) (a) Strength function R_F (black solid lines) of ^{100}Sn . Its single-particle decomposition, multiplied by a factor of three ($R_{F_{lj}} \times 3$), is represented with colored solid (dashed) lines for neutrons (protons). (b) Spectra of emitted particles "shifted" from their single-particle energies are plotted in colored solid (dashed) lines for neutrons (protons). Their sum appears in black.

FIG. 6: (Color online) Same as Fig. 5 for ^{132}Sn .

IV. CONCLUSIONS

Using a simple single-particle decomposition, the microscopic structure and (direct) decay of the GMR in some spherical nuclei has been studied. The GMR strength was obtained by two techniques: (i) from the real-time small amplitude monopole response and (ii) from the spectra of emitted nucleons. In (ii), each microscopic contribution has to be shifted by the single-particle energy of the hole state.

Although both techniques lead to almost identical monopole strengths, their microscopic structure (i.e., their decomposition onto the single-particle quantum numbers l and j) may be very different. This is understood by the fact that, although GMR energies are usually above the nucleon emission thresholds, only part of the particle-hole states lie in the continuum. Those which are bound are coupled to unbound states via the RPA residual interaction which is responsible for the collectivity of the vibration. This is illustrated, e.g., in monopole spectra of neutron-rich tin isotopes: although both protons and neutrons contribute to the monopole vibration, only neutrons can be emitted because protons are more

bound and have to overcome the Coulomb barrier.

A major improvement of the method would be to include two-body correlations, like pairing interaction and collision terms. The latter are known to be responsible for the additional spreading width of giant resonances as well as a fragmentation of their strength function [31]. They are also expected to modify the structure of the spectra of emitted nucleons by coupling 1p1h states to 2p2h. A first step would be to use the Extended-TDHF [32–34] or the time-dependent Density-Matrix [35–37] formalisms. Because of computational limitations, spherical symmetry (and thus, only monopole vibrations) might be first considered.

Acknowledgments

We thank T. Lesinski for providing the routine for computation of Bessel functions. We are also grateful for comments and discussions with Ph. Chomaz and D. Lacroix at the early stage of this work. Partial support from ARC Discovery grants DP06644077 and DP110102858 is acknowledged.
